ABSTRACT

Dazomet is one of the three major pesticides that generate methyl isothiocyanate (MITC). It is used as a soil fumigant less widely than metam sodium, but it has been used increasingly in recent years due to more restrictions on metam uses. To implement mitigation for pesticides that generate MITC, Department of Pesticide Regulation (DPR) initiated a pilot air monitoring study to collect information on MITC emissions from a dazomet field application. The study was conducted concurrently with a nursery research experiment on May 6, 2005. The experiment was to evaluate multiple fumigant application efficacies in a pre-plant strawberry field. The fumigant application was a factorial design of four replicates for each of three treatments, methyl bromide/ chloropicrin, Telone only, and Telone + Basamid, randomized on 12 small plots. Each plot was rectangular with dimensions of 100' x 22', a total of 0.2 acre for each treatment. DPR collected methyl bromide samples collocated with MITC sampling as a reference. The dazomet application was surface broadcast using a drop spreader, no tarp, and sprinkler irrigation. Its application rate was 235 lb/ac of Basamid (26.1 gram/m² of active ingredient of dazomet, equivalent to 11.7 gram/m² of MITC). The methyl bromide application was broadcast, shanked to 12 inches depth, and tarped. Its application rate was 370 lb/ac of methyl bromide/ chloropicrin (67/33), i.e. 27.8 gram/m² of active ingredient of methyl bromide.

The highest individual sample air concentrations were 129 µg/m³ for MITC and 133 µg/m³ for methyl bromide. Both MITC and methyl bromide maximum air concentrations during each sampling period declined over time. The highest 24-hour time-weighted average (TWA) concentration of 66.9 µg/m³ for MITC (18 hours) and 103 µg/m³ for methyl bromide (22 hours) occurred during the first sampling day. The highest individual flux estimates were 53.8 µg/m²-s for MITC and 87.9 µg/m²-s for methyl bromide during the first 6 and 10 hours after start of MITC and methyl bromide application, respectively. The modeled flux profiles showed a general decline over time. Significant rain and higher relative humidity may have affected the MITC and methyl bromide air concentrations and flux estimates during sampling periods 6 and 8. The highest emission ratio to the application rate in each sampling period was estimated to be 9.93% for MITC during the first 6 hours and the highest 24-hour emission ratio was estimated at 24.1 % for methyl bromide during the first monitoring day of 22 hours. The total amount of MITC released to air from the application field during the 5-day monitoring study was approximately 43.1 % of the equivalent applied amount of MITC and 53.4 % of the applied methyl bromide.

ACKNOWLEDGMENTS

We would like to express our sincere appreciation to many people who contributed to this study. We are indebted to the nursery corporation for allowing us to collect samples during their field experimental study. We gratefully acknowledge cooperation provided by Field Research Director, Dr. Mike D. Nelson, and Manteca Facility Manager, Bill Barksdale, for their leadership to the field applications and timely communications. We appreciate Mr. Robert Fritts Jr., Field Development Manager of the chemical application company for his cooperation and information regarding the field application.

We also thank the San Joaquin County Deputy Agricultural Commissioner, Gary Stockel, for his cooperation and providing us with valuable information of related pesticide applications around monitoring area.

We specially acknowledge the California Department of Food and Agriculture's chemists for their dedication in timely analysis of the samples. Many thanks also to Gura Gurusinghe and Roger Sava for their support and contribution to the essential teamwork of collecting field samples. We also appreciate Roger Sava and Cindy Garretson for their efforts in soil sampling and analyses. Thanks to Bruce Johnson for his review and comments on the manuscript.

INTRODUCTION

The California Department of Pesticide Regulation (DPR) declared methyl isothiocyanate (MITC) and all pesticidal sources of MITC as toxic air contaminants in June 2003 (DPR, 2003). Metam sodium, metam potassium, and dazomet are three major pesticides that generate MITC. Metam sodium has been widely used as an agricultural soil fumigant and its environmental concentrations have been intensively studied. Metam potassium has a chemical structure similar to metam sodium and would be expected to show similar behavior in the environment. Unlike the metams' open structure, dazomet consists of a heterocyclic ring containing carbon, nitrogen, sulfur, and hydrogen. Therefore it would be expected to have a different degradation rate and pathway. Dazomet use is much less than metam sodium and information on its environmental impact is limited (Wales, 2002). DPR had no field study information on dazomet-related MITC air concentrations or flux before August 2005. DPR initiated studies to determine MITC air concentrations or flux estimates adjacent to dazomet treated fields.

Dazomet is a broad-spectrum soil fumigant used to control soil fungi, nematodes, weeds, and soil insect pests. In moist soil, dazomet decomposes rapidly to methyl (methylaminomethyl) dithiocarbamic acid which further degrades to MITC, formaldehyde, hydrogen sulfide, and methylamine. One manufacturer of dazomet products reported it was this combination of volatile gases that resulted in the fumigant activity (BASF, 1989). The decomposition of dazomet can occur in as little as 10 to 15 minutes (Thomson, 1989). A reported aerobic soil half-life (50% dissipation time) was 18 hours at pH 5.8 in a loamy sand soil (DPR, 1999). Soil moisture may be the key factor in dazomet decomposition. Soil temperature, pH, and soil type all affect on the rate of degradation (Wales, 2002; Munnecke and Martin, 1964; Sczerzenie et al., 1987).

Dazomet agricultural use in California has been increasing every year from 2000 to 2004, according to DPR's pesticide use database. Of the total reported dazomet use, 202,623 pounds of active ingredient in 2000-2004, 68% was for right of way applications, 24% for crop production, 6% for landscape maintenance, and 2% for other uses. For right of way applications, a major product containing dazomet was Ultrafume. Ultrafume was usually applied around electrical and telephone poles using a deep injection method to protect against pest damage. For crop production, Basamid, a granular soil fumigant, was used with surface or incorporated broadcast applications with or without tarp. From 2000 to 2004, a total of 48,774 pounds (24% of the 202,623 pounds) of active ingredient dazomet was applied for crop production. Ninety-two percent of the 48,774 pounds was used in nurseries (DPR, 2005). Applications in nurseries occur throughout the year.

While Basamid is relatively non-volatile, it produces MITC, which has a high vapor pressure, 16.0 mm Hg at 25 °C (Table 1), and leaves the soil to air via volatilization (Levine et al., 2005). MITC has the potential to drift offsite. DPR's previous monitoring of metam-sodium under condition that would favor maximum emissions of MITC (Wofford et al, 1994) found that MITC levels exceeded the Office of Environmental Health Hazard Assessment's 1-hour Reference Exposure Level (REL) for eye irritation of 1.2 micrograms per cubic meter ($\mu\text{g}/\text{m}^3$) or 0.4 parts per billion (ppb) (Levine et al., 2005).

In efforts to minimize potential adverse human health impacts, DPR is drafting buffer zones for MITC (DPR, 2004). Fumigant studies are conducted to provide a scientific basis for determining effective buffer zones. The Environmental Monitoring (EM) Branch of DPR conducted this dazomet and methyl bromide monitoring in May 2005 at a nursery in Manteca, CA. The objectives of this study were to measure air concentrations of MITC and methyl bromide after a multiple fumigant application, estimate the flux associated with the chemicals and application methods, characterize the flux profiles during the monitoring period, and estimate the emission ratios of MITC and methyl bromide during the first 48 hours (DPR, 2004).

MATERIAL AND METHODS

Pesticides Monitored

The dazomet product monitored in this study was Basamid® Granular soil fumigant. Basamid® Granular contains 99 percent (%) active ingredient of dazomet (tetrahydro-3,5,-dimethyl-2-H-1, 3, 5,-thiadiazine-2-thione) and 1% inert ingredients. It is typically applied by spreader to soil surface and immediately tilled into the soil with a rototiller (Wales, 2002), or applied with a belly grinder to prepared soil, then immediately tarped or irrigated thoroughly, wetting the soil according to the label instruction (BASF, 1998). Basamid® Granular label recommends application rates from 225 to 530 pounds per acre depending on soil texture, pH, organic matter content, and the type of pests to be controlled (BASF, 1998).

The methyl bromide product used in this study was 67-33 Preplant Soil Fumigant, a pressurized liquid composed of 67.0 % methyl bromide and 33.0% chloropicrin. It is applied directly in soil to the desired depth with appropriate equipment. Methyl bromide is biologically active for soil fumigation. Some physical and chemical properties for MITC, dazomet, and methyl bromide are listed in Table 1.

Table 1. Physicochemical properties of MITC, dazomet and methyl bromide^a

| | MITC | Dazomet | Methyl bromide |
|---|----------------------------------|--|--------------------------------|
| Molecular formula | C ₂ H ₃ NS | C ₅ H ₁₀ N ₂ S ₂ | CH ₃ Br |
| Molecular weight | 73.12 | 162.3 | 94.9 |
| Solubility in water (ppm) | 8.61 x10 ³ (25 °C) | 3.63 x10 ³ (20 °C) | 1.32 x10 ³ (25 °C) |
| Vapor pressure (mm Hg) | 16.0 (25 °C) | 9.88 x10 ⁻⁶ (25 °C) | 1.42 x10 ^{3b} (25 °C) |
| Henry's law constant (atm-m ³ /mole) | 1.79 x10 ⁻⁴ (25 °C) | 2.57 x10 ⁻¹⁰ (20 °C) | 0.134 ^c (25 °C) |
| Hydrolysis half-life (days) | 20.4 (pH 7, 25 °C) | 0.146 (pH 7, 25 °C) | 9-29 (18 °C) 8-28 (30 °C) |
| Aerobic soil half-life (days) | 0.5 – 50 ^d (25 °C) | 0.75 (pH 5.8, loamy sand) | 0.158-20 (23 °C) |

Field Description

The application field was located in the San Joaquin Valley, San Joaquin County, California. The treatment area was approximately 0.5 acre on the southern edge of a 27-acre flat field. The field was open on the north and surrounded by almond orchards on the other three sides. A house was located on the south side. An unoccupied temporary workers' living facility was at the northeast corner of the field and a county road was between the field and almond orchards (Figure 1). There were no reported MITC generating pesticides and methyl bromide applications in the area within this same township between May 3 and May 10, 2005 (Gary Stockel, personal communication).

Pesticide Application

DPR's monitoring study was conducted in cooperation with a nursery research on multiple soil fumigant applications. The research was to evaluate efficacy for three preplant treatments of soil fumigants, methyl bromide / chloropicrin, Telone C35, and Basamid / Telone C35, in a strawberry field. The field plot design was a randomized complete block with four replicates for each of the three pesticide treatments. Twelve rectangular plots were arranged in two columns and six rows. Each plot was 100' x 22' (two passes of the flat-fume rig), approximately 100' apart between the two columns and 13' to 20' between rows (Figure 2). Both the Telone C35 and methyl bromide/chloropicrin were applied using a standard flat-fume soil fumigation rig. The methyl bromide/chloropicrin was shanked in to a 12" depth and tarped. The Telone C35 was shanked in to an 18" depth, but not tarped. Following the application, the shank gap was closed and soil was compacted by a ring roller. The Basamid was broadcast applied using a drop spreader (Figure 3) after the Telone C35 application. Following the Basamid application, sprinkler irrigation was immediately applied from 14:00 to 15:00 for surface sealing and pesticide activation. Post-application irrigation was conducted twice on the next day (May 7, 2005), once in the morning and once in the afternoon. Each ran half an hour with a quarter inch of water (oral communication with nursery research staff). There was another irrigation scheduled in the following morning, but cancelled due to rain. The local weather station (Station MSD of California Data Exchange Center) reported a total of 0.28 inches of rain on May 8, 2005.

The pesticide application rates are listed in Table 2. The application was started on May 6, 2005 with methyl bromide/ chloropicrin treatment from 9:04 to 9:25 am. An equipment problem delayed Telone C35 treatment until 11:42 to 12:42. The Basamid treatment was conducted from 12:43 to 13:22.

Table 2. Pesticide application rates

| Pesticide | Total amount applied | Area applied | Application Rate |
|-------------------------------------|-----------------------------|---------------------|-------------------------|
| Basamid | 47 lbs. | 0.2 ac. | 235 lbs./ac. |
| Telone C35 | 18.5 gal. | 0.4 ac. | 46.3 gal./ac. |
| Methyl bromide/chloropicrin (67/33) | 74 lbs. | 0.2 ac. | 370 lbs./ac. |

Figure 1. Application field aerial view (North is at the top)

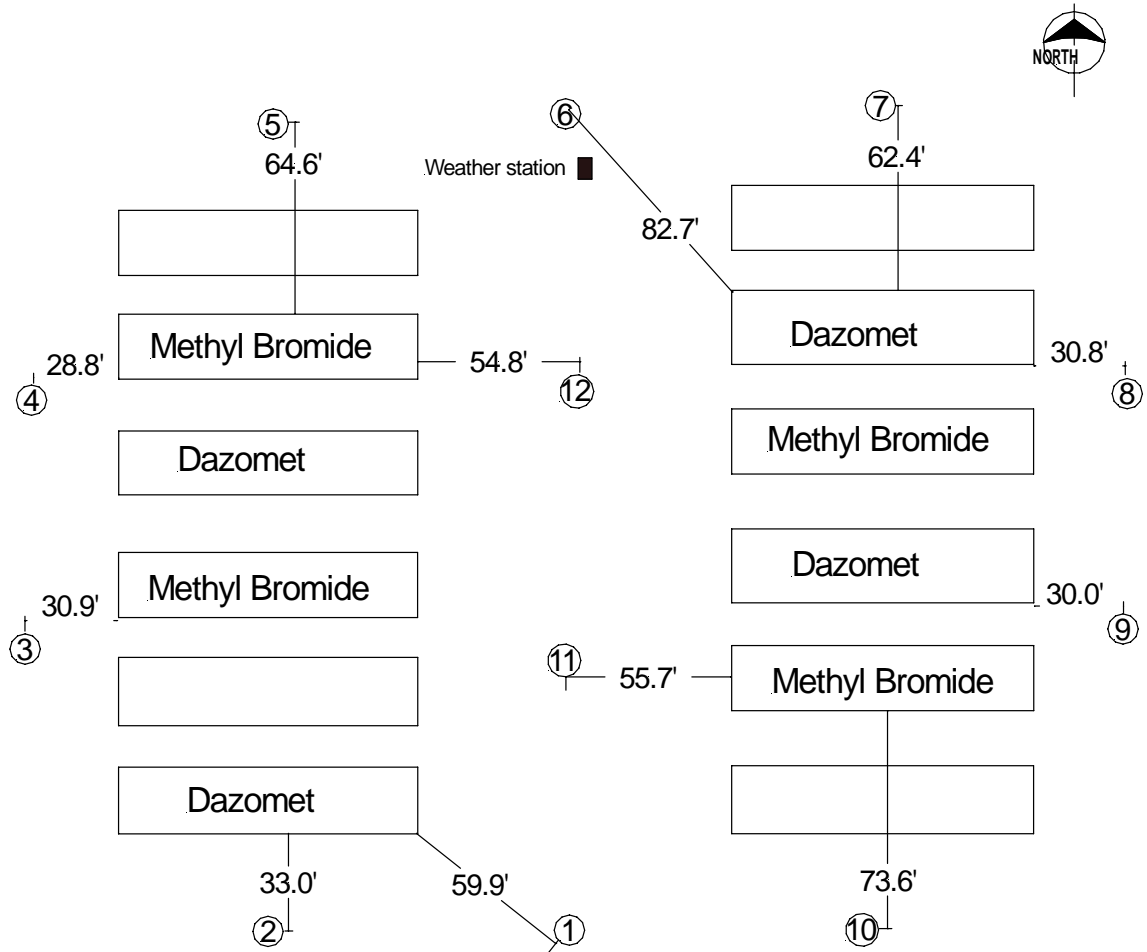

Figure 2. Application plots, sampler locations, and approximate distances*

*Only monitored chemicals are shown in the treatment plots. The number in circle indicates the sampler identification.

Figure 3. Basamid application

Air Sampling

Twelve sampling locations were located around the study plots at distances of approximately 30 and 60 feet (ft) from the edge of the treatment plots (Table 3 and Figure 2). On each sampling location, two air sampling pumps (SKC#224-PCXR) were set up. One pump was equipped with a 400/200 mg two-section Anasorb coconut shell charcoal (CSC) tube (SKC #226-09) at an airflow rate of 1.5 liters per minute (L/min) for MITC. The other was connected to two consecutive petroleum charcoal sorbent tubes, a 400 A-tube and a 200 mg B-tube (SKC #226-38-02), and adjusted to an airflow rate of 15 milliliters per minute (ml/min) for methyl bromide. Background air samples were collected the evening prior to the fumigant applications. Application samples were turned on at the scheduled start time of 7:00 am on May 6, 2005. Due to technical problems encountered during application, the methyl bromide/chloropicrin applications started at 9:04 AM and the Basamid application started at 12:43 PM. Samples were collected approximately every 12 hours, one hour before sunset and one hour after sunrise, a total of ten sampling periods for five days (Table 4). At the beginning and the ending of each sampling period, the flow rate for each sampler was measured, recorded and calibrated if necessary. Flow rates were measured with a DryCal® Primary Flowmeter. The sampled sorbent tubes were capped and immediately placed on dry ice. Details of air sampling and equipment operation, calibration, and maintenance are described in DPR's Standard Operation Procedure (Wofford, 2001)

Table 3. Sampler identification and distances from the edge of the application plots

| Sampler Identification | Distance (ft) |
|-------------------------------|----------------------|
| 1 | 60 |
| 2 | 33 |
| 3 | 31 |
| 4 | 29 |
| 5 | 65 |
| 6 | 83 |

| 10 | 74 |
| 11 | 56 |
| 12 | 55 |

Table 4. Timing of the sampling periods

| Sampling Period | Date and Time On | Date and Time Off | Duration (hours) |
|-----------------|------------------|-------------------|--------------------------------|
| background | 5-May 16:35 | 6-May 6:05 | 13.5 |
| 1 | 6-May 7:00 | 6-May 18:52 | 6 (MITC), 10 (methyl bromide)* |
| 2 | 6-May 18:55 | 7-May 6:46 | 12 |
| 3 | 7-May 6:49 | 7-May 18:50 | 12 |
| 4 | 7-May 18:52 | 8-May 7:18 | 12 |
| 5 | 8-May 6:52 | 8-May 18:50 | 12 |
| 6 | 8-May 18:52 | 9-May 7:02 | 12 |
| 7 | 9-May 7:08 | 9-May 18:54 | 12 |
| 8 | 9-May 18:55 | 10-May 6:54 | 12 |
| 9 | 10-May 6:55 | 10-May 18:54 | 12 |
| 10 | 10-May 18:55 | 11-May 6:55 | 12 |

*Sampling pumps ran for 12 hours. However applications for methyl bromide and MITC started at 9:04 am and 12:43 pm, respectively. The actual sampling duration of the first period was 6 hours for MITC and 10 hours for methyl bromide.

Air Sample Handling and Transportation

Prior to monitoring, sample labels with the study number and sample identification numbers were attached to the sorbent tubes. Preparation of sorbent tubes for use with air sampling pumps is described in DPR's SOP FSAI001.01 (Ganapathy, 2003). Chain of custody forms and sample analysis request forms were supplied to field sampling personnel. Field personnel collected field notes, field measurements, sampler location, application data, and weather observations. During sampling, the tube was covered with aluminum foil to protect from direct sunlight. During irrigation or rain, the tube was placed with the air inlet tip downward and wrapped with an aluminum skirt to protect the sample from water damage. The collected samples were packaged and transported according to procedures in DPR's SOP QAQC004.01 (Jones, 1999). All samples were transported to the laboratory for analysis by May 12, 2005. Each sample was accompanied by chain of custody that was signed by each person handling the sample. All samples followed sample receipt log-in and verification procedures described in SOP QAQC003.01 (Hoffman, 1999).

Soil Sampling

Soil samples were collected at two locations for bulk density and moisture content. The locations were at the southwest side and in the middle of the treatment area. These samples were collected at a depth of 6-12 inches. A composite surface soil sample was randomly collected over the treatment area for soil texture analysis. Samples were collected and analyzed in accordance with DPR's SOP FSSO001.00 and SOP FSSO002.0 (Garretson, 1999a and 1999b).

Meteorological Measurements

Wind direction, horizontal wind speed, temperature, solar radiation, and relative humidity were measured by MetOne® meteorological sensors at a height of 10-meter (32.8 feet). The weather station was installed in the middle of the study field approximately 10 ft north of the treatment block (Figure 2). The meteorological measurements were recorded on a Campbell Scientific CR 21X Data logger as a 1-minute average of 1-second instantaneous readings, except for wind direction which was an instantaneous measurement once every minute. The wind direction measurement was with respect to magnetic north. Therefore a declination angle of 14.5° was added to compute the direction with respect to true north. In addition, amount of cloud cover and/or precipitation was noted at each sampling period.

Chemical Analysis

The MITC and methyl bromide were analyzed by the California Department of Food and Agriculture (CDFA) Center for Analytical Chemistry. MITC in the two-section of 400/200 mg coconut shell charcoal tube was desorbed from the sorbent tubes with 5 ml of 0.1% CS₂ in methylene chloride. The extracts were analyzed on a gas chromatograph equipped with a mass selective detector. Methyl bromide in the 400 mg petroleum charcoal A-tube and 200 mg B-tube was extracted and analyzed separately. The extraction was using 5-10 ml of 0.1% ethyl acetate and measurement was using a gas chromatograph equipped with an electron capture detector. The results of A-tube and B-tube were combined in this report.

QUALITY CONTROL AND QUALITY ASSURANCE MEASURES

Quality control and quality assurance measures followed the Chemistry and Laboratory Quality Control Standard Operating Procedure (Segawa, 1995).

Field Sampling and Sample Handling

Background and Collocated Samples

To measure ambient background concentrations, four background samples, two for each chemical monitored, were collected for a 14-hour period prior to the field application. During the field monitoring, two collocated samples, one at the first sampling period and the other at the ninth period, were collected at sampling location 11 for each chemical. The collocated samples, less than a meter apart, provided an estimate of field sampling precision.

Field Spikes, Trip Spike, and Trip Blank

The field and trip spikes were sorbent tubes spiked with a known amount of MITC or methyl bromide in the laboratory, stored on dry ice, and transported to the field. To provide an estimate of reliability of field sampling process, the field spike was treated the same as a field sample, with air flowing through the spiked tube for a sampling period, stored, transported, and analyzed with other field samples. Two field spikes for each chemical were collected with the background samples to avoid contamination from the application.

The trip spike provided an estimate of the integrity of the sample storage and transportation for the round trip between the laboratory and the field. The trip spike was handled the same as the field spikes but without the field run. One trip spike was collected for each chemical.

The trip blank samples were collected by breaking unused tubes and placing them on dry ice. They were handled, stored, transported, and analyzed with other field samples. The trip blank provides an estimate of any contamination during transportation or storage. One trip blank was collected for each chemical.

Trapping Efficiency

Trapping efficiency for MITC air sampling was conducted by spiking MITC standard onto coconut charcoal tube (SKC #226-09) at three levels, 1, 10, and 100 µg/tube, and three replicates for each level. The spiked sorbent tubes were sampled for 24 hours using personal air sampler pumps (SKC#224-PCXR) with an airflow rate of 1.5 L/min. The average recoveries were 79.8%, 77.6%, and 65.9% for the levels 1, 10, and 100 µg/tube, respectively. The overall recovery was 74.5%. Significant amounts of MITC were detected in all of the second section (B) of the sorbent tubes (Appendix II), indicating the possibility of breakthrough at all levels in a 24-hour sampling period.

Trapping efficiency for methyl bromide air sampling was intensively studied by comparison of charcoal tube and SUMMA canister recoveries (Biermann and Berry, 1999). It was concluded that for most of the data in a humidity range of 20% to 80% and concentrations between 20 ppb and 2000 ppb, no major effects of either humidity or concentration were found. The average recovery was 49% ± 7% (standard deviation) for the sorbent tubes.

Storage Stability

The results of storage stability study (Biermann and Berry, 1999) indicated that frozen air samples of methyl bromide were stable for a week before extraction. MITC samples were reported to be stable for two weeks (Wofford et al., 2003; Leung, 1982)

Chemical Analysis

Method Validation

For validation of the MITC analytical method, the laboratory spiked three sets of tubes at levels of 2, 20, and 200 ppt, respectively. Each set consisted of five replicates. Recoveries ranged from 93 to 111% and overall average was 101% (CDFA, 2004).

Method validation for methyl bromide was conducted by spiking two sets of tubes at levels of 1 and 20 µg/tube, respectively. Each set consisted of three replicates. Recoveries were 85.7%±3.83% and 83.9%±1.99% for 1 and 20 µg/tube, respectively (CDFA, 1994).

In this report, upper and lower control limits and warning limits for QC were determined by adding or subtracting 2X and 3X standard deviations (SD) from the average percent recovery of the method validation. The procedures and definitions for the EM QC program are listed in SOP QAQC001.00 (Segawa, 1995).

MITC validation (15 samples)

| Control Limits | Recovery (%) |
|---------------------|--------------|
| Upper control limit | 117 |
| Upper warning limit | 110 |
| Lower warning limit | 84.7 |
| Lower control limit | 78.2 |

Methyl bromide validation (6 samples)

| Control Limits | Recovery (%) |
|---------------------|--------------|
| Upper control limit | 107 |
| Upper warning limit | 98.4 |
| Lower warning limit | 64.2 |
| Lower control limit | 55.6 |

Method Detection Limits and Reporting Limits

The method detection limit (MDL) is the lowest amount of an analyte that a method can detect reliably. MDL for MITC was determined by spiking seven sorbent tubes with small amounts of standard and calculating the mean at 99% of confidence period. For methyl bromide, it was determined with sample size of four. The MDLs were 0.0206 µg/sample for MITC (CDFA, 2004) and 0.2 µg/sample for methyl bromide (CDFA, 1994).

The reporting limit (RL) refers to the smallest amount of a chemical that can be reliably quantified. The laboratory determined RL normally ranges from 1 to 5 times the MDL. The RLs were 0.05 µg/sample for MITC and 0.2 µg/sample for methyl bromide in this study.

Continuing Quality Control and Control Limits

Continuing proficiency of analysis is demonstrated through ongoing analysis of laboratory spiked samples analyzed with each set of up to ten field samples. The control limits are used as a check on the results of the continuing quality control spikes. The upper and lower warning and control limits are set at ± 2 and ± 3 standard deviations of the percentage recovery using the data from the method validation study for each analyte. The exceedance of a warning limit can indicate a possible problem that should be checked, whereas any spiked sample outside the control limits may require the set of samples associated with the spike to be reanalyzed.

RESULTS AND DISCUSSION

Calculation of Air Concentration

The sample concentrations were calculated as amount of chemical removed from a volume of air moving through the sampling media during a sampling period. The laboratory analytical results were reported in µg/sample. The air concentrations were converted from µg/sample to µg/m³ with the following calculations:

$$\frac{\text{Sample concentration } C (\mu\text{g/sample}) * 1000 (\text{L/m}^3)}{\text{Flow rate } R (\text{L/min}) * \text{Time } T (\text{minutes/sample})} = \frac{1000 * C}{RT} (\mu\text{g/m}^3)$$

Concentrations can be converted from $\mu\text{g/m}^3$ to ppb:

at 25 °C (298 °K) and 1 atmosphere, $1 \mu\text{g/m}^3 = 24.45/\text{molecular weight (MW)} \text{ ppb}$

Therefore $1 \mu\text{g/m}^3 \text{ MITC} = 24.45 / 73.12 \text{ ppb MITC} = 0.3344 \text{ ppb MITC}$

$1 \mu\text{g/m}^3 \text{ methyl bromide} = 24.45/94.9 \text{ ppb methyl bromide} = 0.2576 \text{ ppb methyl bromide}$

In the following results presentation and discussion, the sampling period numbering refers to sampling sequence. The site numbering is the site identification and its location is shown on Figure 2.

Analytical and calculated results were reported to 2 or 3 significant figures. When a sample was invalid for a known reason, its analytical result was reported as not available (NA). When an analyzed result was below the RL, none detected (ND) was reported, and the quantity of half the (RL + MDL) for MITC or half the RL for methyl bromide was used for concentration calculations unless specified in this study.

When the results were presented as a 24-hour time weighted average (TWA), it was an average of two sampling periods, 12-hour daytime and 12-hour night time for a given day, unless otherwise specified in this study.

Results of Air Monitoring

Figures 4-7 provide a side-by-side graphical comparison of the sample concentrations of MITC and methyl bromide with the wind direction and speed during each sampling period. On the left side of the figure are the wind roses using WRPLOT View v. 3.5 (Lakes Environmental, 2000) for the frequency distribution of wind direction and speed. The spokes represent the direction the wind blew to, while the length represents the duration in that direction. The rings represent different percentages of time that the wind was blowing in a particular direction. The color code refers to the average speed in a given direction. The correspondence of wind speed in unit of meter/second to color code is listed on the figure legend. On the right side are the maps of field plot treatments, sampler locations, and monitoring results. The number in a circle refers to the sampler identity. The sample concentrations in unit of $\mu\text{g/m}^3$ for MITC and methyl bromide are on the top and bottom, respectively, of the sampler identities. ND means none detected.

Figure 4. Wind-rose diagram along sample concentrations for sampling periods 1-3
(See footnote in Figure 7)

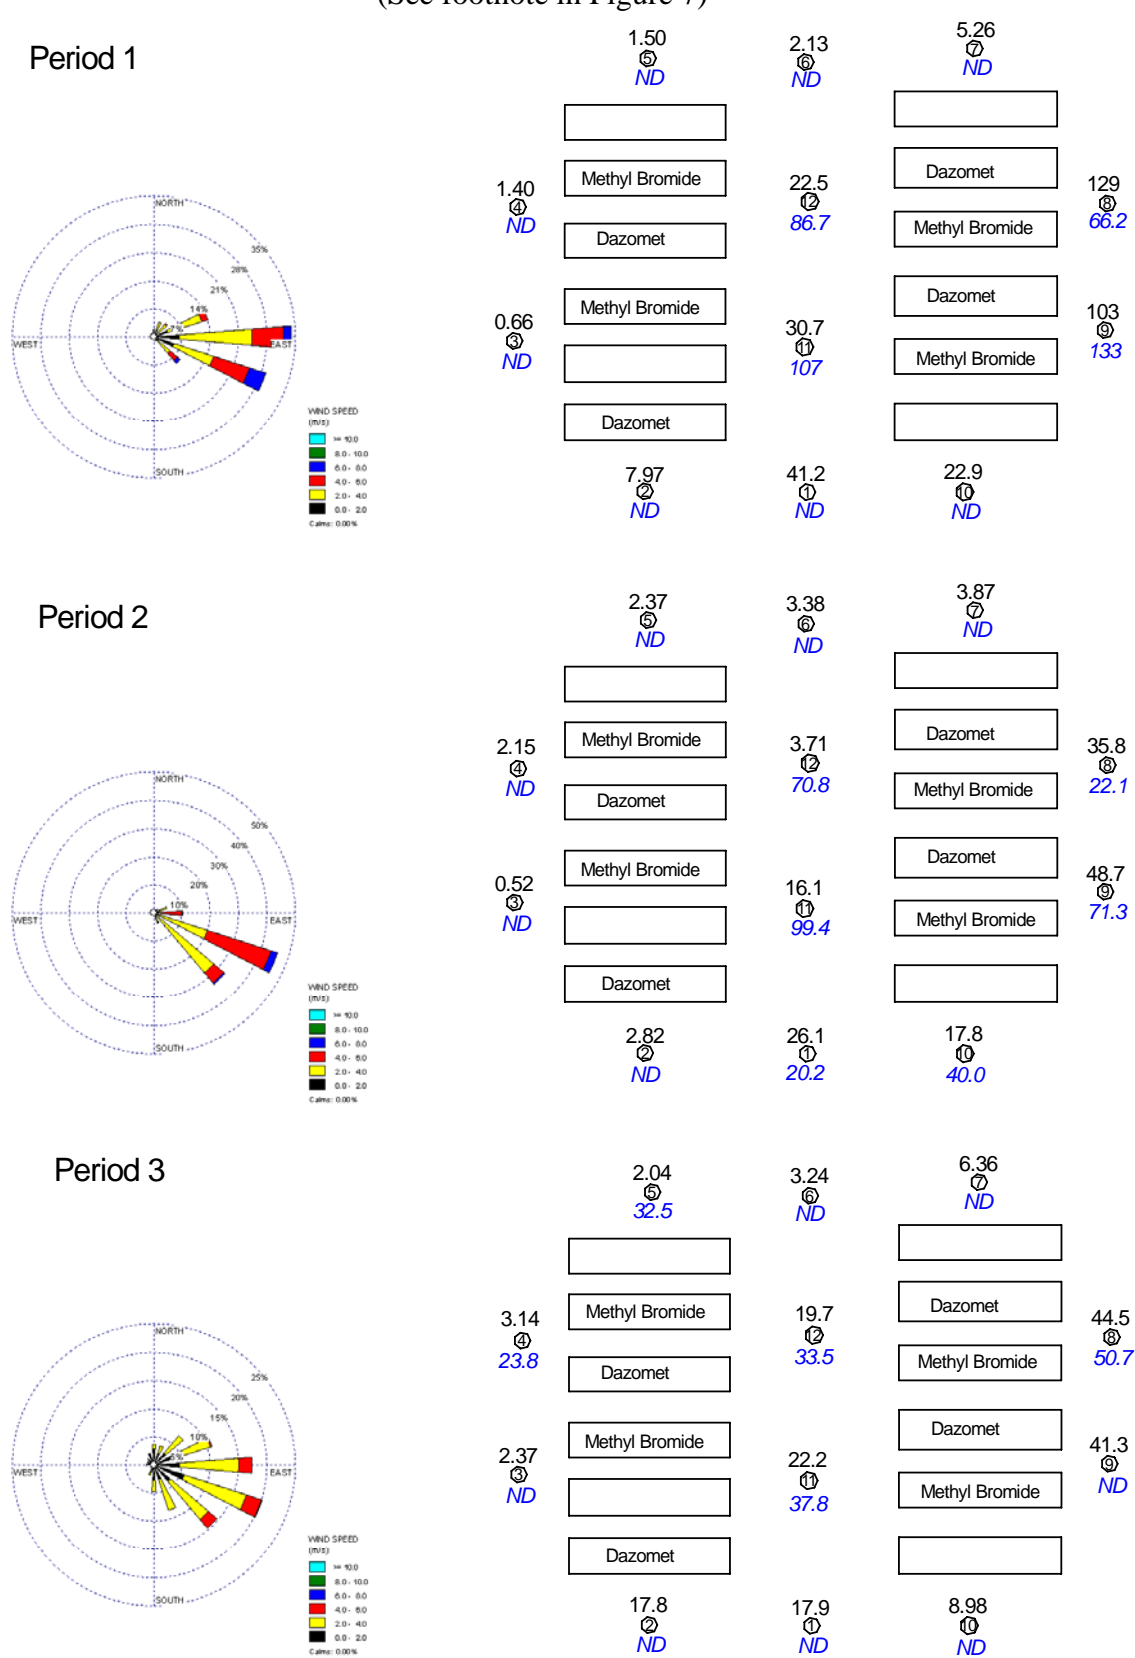

Figure 5. Wind-rose diagram along sample concentrations for sampling periods 4-6
 (See footnote in Figure 7)

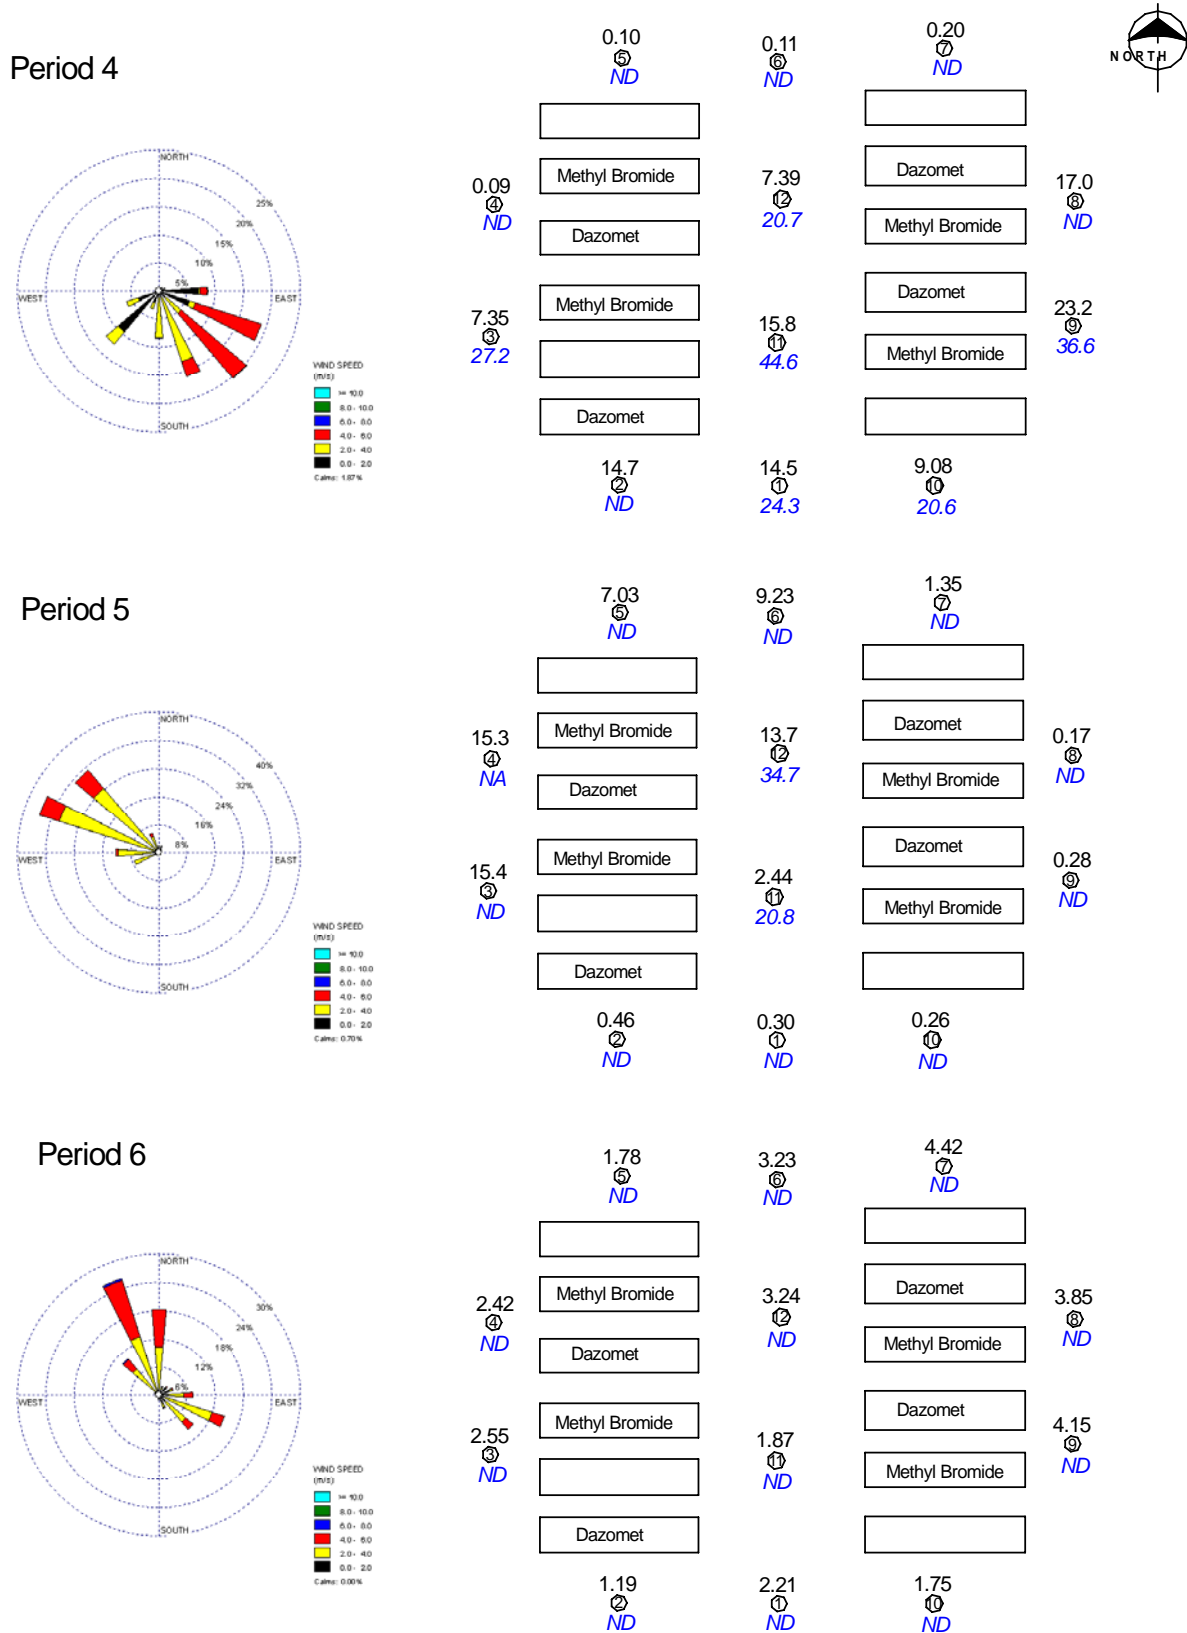

Figure 6. Wind-rose diagram along sample concentrations for sampling periods 7-9
 (See footnote in Figure 7)

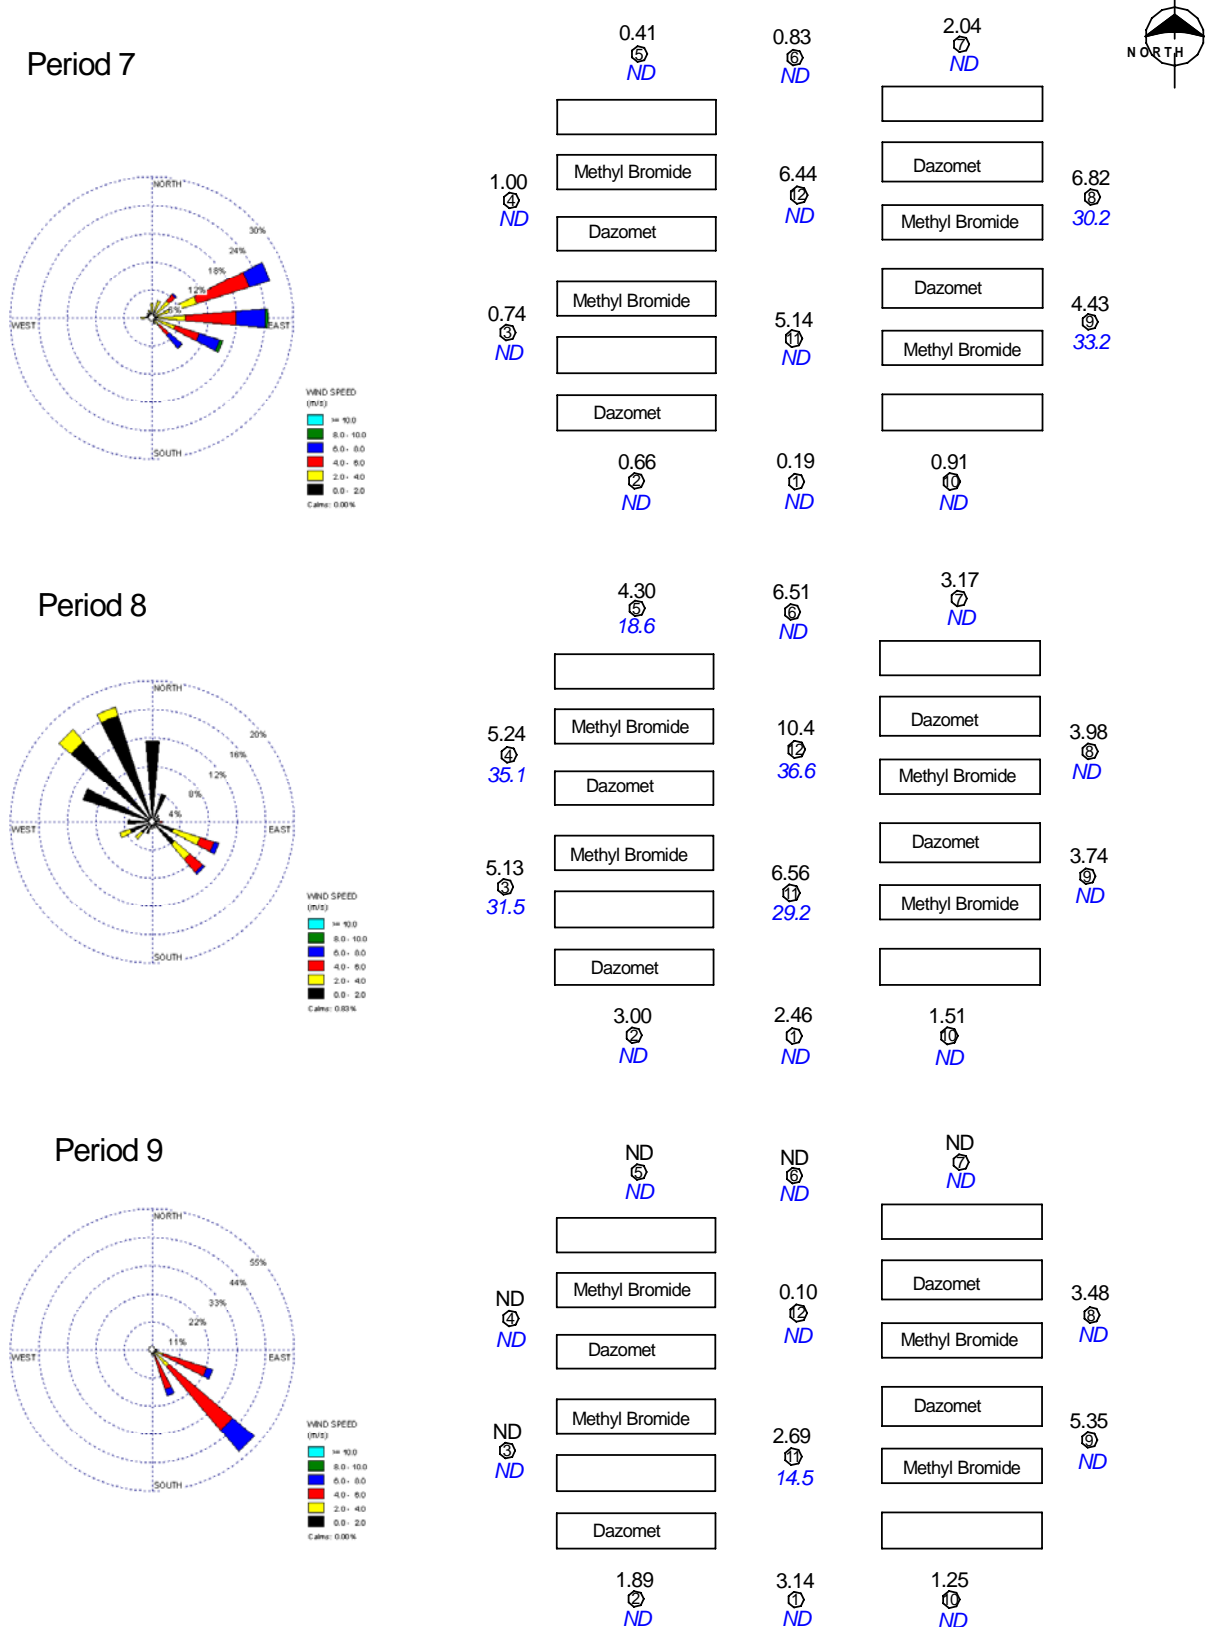

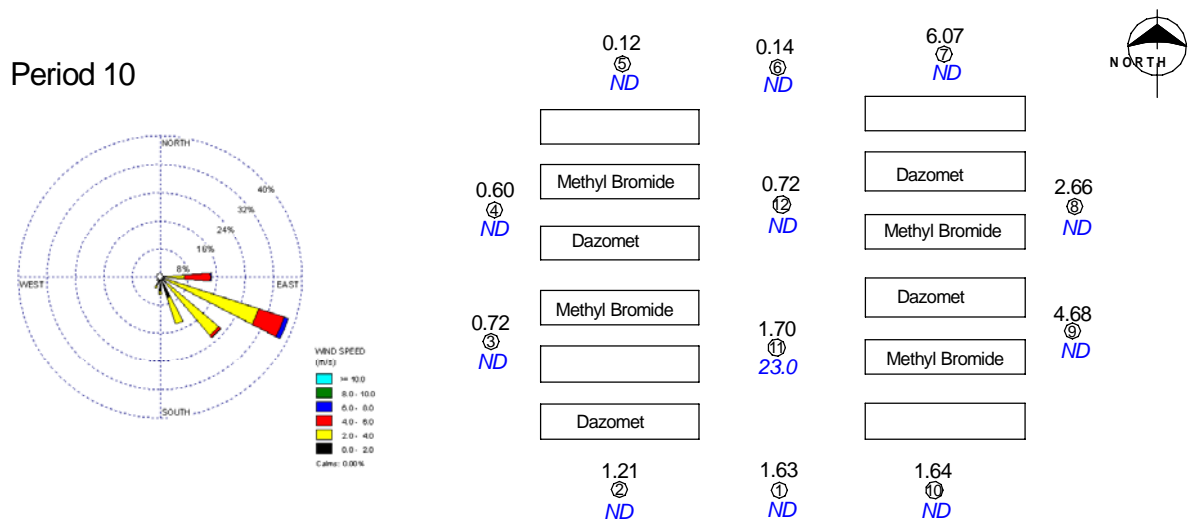

Figure 7. Wind-rose diagram along sample concentrations for sampling period 10*

*On the wind rose, the spoke refers to the direction the wind blew to, the length to the percentage of time the wind blew in the direction, the color code to the average speed in the direction. On the field plot map, the number in a circle refers to the sampler identity, the number on the top or bottom for the sample concentration of MITC or methyl bromide, respectively, in unit of µg/m³. ND means none detected.

In general, air sample concentrations were strongly affected by wind speed and wind direction. For the monitoring periods with lower wind speeds, such as periods 8 (Figure 6), or wind blowing to two opposite directions, e.g. periods 6 and 8 (Figures 5 and 6), the monitoring results were relatively low and evenly distributed. During periods with dominant wind direction and higher wind speeds, the higher sample concentrations corresponded to the downwind sites, e.g. sites 8 and 9 during the period 1 (Figure 4). Even during periods 9 and 10, both MITC and methyl bromide could still be detected at site 11 (Figures 6 and 7).

MITC

A total of 128 samples for MITC were collected during the study, including two background, two collocated, two field spikes, one trip spike, and one trip blank sample. The two background samples did not contain any detectable amount of MITC.

The results for MITC at each sampling location in each sampling period are listed on Table 5. The highest individual sample concentration, 129 µg/m³, occurred during the first sampling period at sampling site 8 (Table 5), located 31 ft from the east edge of the application block (Figures 2 and 4). The maximum air concentration of MITC during each sampling period (12 hours except for the first period which was 6 hours) is listed on Table 7. In general, the maximum air concentration declined with time after application except that the lowest one occurred during the sampling period 6 and increased slightly during periods 7 and 8 (Figure 8). The highest maximum 24-hour of TWA concentration was 66.9 µg/m³ (18 hours) during the first sampling day (Table 8), at sampling site 8.

*None detected. MDL for 6-hour sample = $0.04 \mu\text{g}/\text{m}^3$, 12-hour sample = $0.02 \mu\text{g}/\text{m}^3$

¹average of collocated samples.

Methyl Bromide

A total of 128 samples for methyl bromide were collected from field including two background, two collocated, two field spikes, one trip spike, and one trip blank samples. Two samples were invalid due to loss of their A-tube samples during laboratory extraction. On two other samples, their B tube samples were lost during extraction. The results of A-tubes were used for these two samples since most of B-tubes were nondetectable. The two background samples did not contain any detectable amount of methyl bromide.

The results for each sampling location in each sampling period are listed on Table 6. Approximately 75% of the samples were non-detects. In part, this may have been due to the small application areas and consequent, low application mass. The highest individual sample concentration, $133 \mu\text{g}/\text{m}^3$, occurred during the first sampling period at sampling site 9 (Table 6), located 30 ft from the east edge of the application block (Figures 2 and 4). The maximum 12-hour (10 hours for the first sampling period) air concentration of methyl bromide during each sampling period is listed on Table 7. In general, the maximum air concentration declined with time after application except for periods 7 and 8 (Figure 8). The pattern of the maximum air concentration was similar to MITC with the lowest during the sampling period 6 and increasing during periods 7 and 8. The highest maximum 24-hour of TWA concentration was $103 \mu\text{g}/\text{m}^3$ (22 hours) during the first sampling day (Table 8), at site 11 located in the middle of the application block and 55.7 ft from the closest edge of the methyl bromide application plot (Figure 2 and 4).

*The first sampling day was 18 hours for MITC and 22 hours for methyl bromide.

Soil and Weather Characteristics

Soil texture was characterized as loamy sand consisting of 86.5% sand, 7% silt, and 6.5% clay in the particle size diameter less than 2.00 mm portion (96.65%) of the soil sample. There were 3.35% of total soil particles with diameter greater than 2.00 mm. Bulk density was $1.87 \text{ g}/\text{cm}^3$. Soil moisture was 8.44% and pH was 7.25. All soil sample results were averages of duplicate samples.

Sky cover during sampling ranged from clear and sunny to overcast (Table 9). On the third day, May 8, 2005, sampling periods 5 and 6, it rained intermittently with hourly precipitation from 0 to 0.08 inch and a total of 0.28 inches of rain that day according to regional weather station (Location: San Joaquin River at Mossdale Bridge, Station ID: MSD, Sensor number: 2, CDWR, 2005). Average wind speed, wind direction, air temperature and relative humidity during each sampling period are listed in Table 9 and detailed records in one-minute increments measured by MetOne® meteorological sensors are available upon request. There was no apparent relationship between average and maximum air concentrations of MITC or methyl bromide versus average

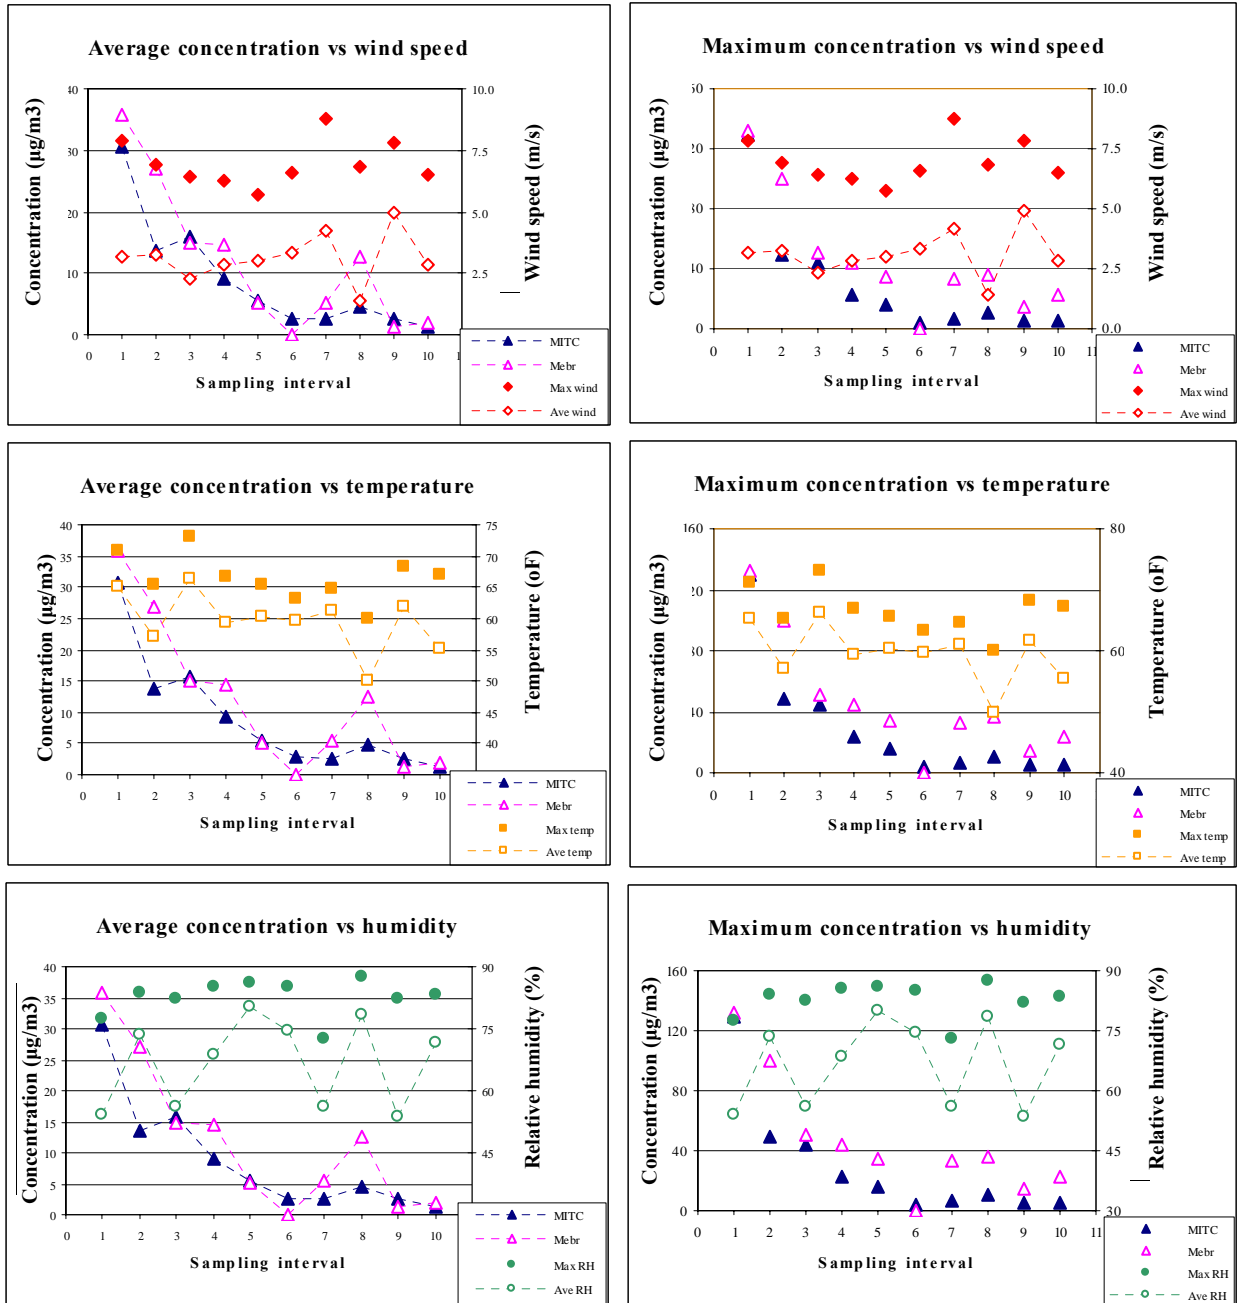

and maximum wind speed, temperature, and relative humidity of each sampling period (Figure 9) over time because the dominant effect was the chemical depletion.

Table 9. Average wind speed, wind direction, air temperature and relative humidity

| Sampling Period | | Cloud cover | Wind speed difference (night-day) | | Wind from Direction 0-360° | Temperature °F | Relative Humidity % |
|------------------------|-------|---------------------------|--|-------|-----------------------------------|-----------------------|----------------------------|

Average and maximum air concentrations of MITC and methyl bromide versus average and maximum wind speed, temperature and relative humidity from each sampling period

Results of Modeling

To estimate MITC and methyl bromide flux and emission ratio during this study, the U.S. EPA ISCST3 model was used to calculate MITC and methyl bromide flux as described by Johnson et al. (1999). The model requires input of location of the treatment areas (source), sampling locations (receptors), and the meteorological data (Met1® data). The treatment areas and sampling locations were mapped in an x and y coordinate system. The meteorological data were collected with a Met1® weather station near the field, and were averaged over 1-hour periods. The model results and measured results were compared through linear regression analysis for each sampling period. The slope of the regression line was used to estimate flux. Detailed modeling information is provided in Appendix III.

The flux estimate was used to calculate the emission ratio, which is the amount of chemical released into air during a given period as a percentage of the effective application rate. The effective application rate is the amount (g) of the target chemical applied to the area (m²). In this study, the target chemical MITC was assumed to be in 1:1 stoichiometric relationship to the active ingredient of dazomet, which comprised 99% of the formulated product, Basamid. The target chemical methyl bromide comprised 67.0% of the formulation of 67-33 Preplant Soil Fumigant product.

$$MITC \text{ emission}(\%) = 100 * \left[\frac{\text{flux} \left(\frac{ug}{m^2 s} \right) * 10^{-6} \left(\frac{g}{ug} \right) * \text{time}(\text{sec onds})}{\text{effective application rate}, 11.7 \left(\frac{g}{m^2} \right)} \right]$$

where the effective application rate was calculated as:

Basamid application rate = 47 pounds * 453.4 g/pound / (0.2 acre * 4047 m²/acre) = 26.3 g/m².

Active ingredient dazomet application rate = 26.3 g/m² * 99% = 26.08 g/m².

Since molecular weight of dazomet and MITC is 162.3 and 73.1, respectively, the effective MITC application rate = 26.08 g/m² * 73.1/162.3 = 11.7 g/m².

$$Methylbromide \text{ emission}(\%) = 100 * \left[\frac{\text{flux} \left(\frac{ug}{m^2 s} \right) * 10^{-6} \left(\frac{g}{ug} \right) * \text{time}(\text{sec onds})}{\text{effective application rate}, 27.8 \left(\frac{g}{m^2} \right)} \right]$$

where the effective application rate was calculated as:

Soil fumigant application rate = 74 pounds * 453.4 g/pound / (0.2 acre * 4047 m²/acre) = 41.5 g/m².

Active ingredient methyl bromide (67%) application rate = 41.5 g/m² * 67% = 27.8 g/m²

MITC

The four plots treated with Basamid and Telone C35 were represented as four separate sources of MITC. Modeling was conducted with an initial emission rate of 100 $\mu\text{g}/\text{m}^2\text{-s}$ at ground level, and weather data measured from 1:00 pm, May 6 to 7:00 am, May 11 because the Basamid application started at approximately 12:45 pm, May 6, 2005.

The modeling results are listed in Table 10. The regressions of the measured and modeled concentrations were significant at $P=0.05$ for each sampling period except for the Period 8. The data for the Period 8 were sorted, and the sorted values were regressed. The flux estimate was highest (53.8 $\mu\text{g}/\text{m}^2\text{-s}$) during the application period (Period 1) and decreased over time except for periods 7 and 9. The 18-hour time weighted average (TWA) flux estimate for the first two sampling periods was 33.8 $\mu\text{g}/\text{m}^2\text{-s}$ (Table 10).

The emission ratio for each sampling period, 24-hour, and cumulative period (Table 11 and Figure 10) was calculated based on the flux estimate and the effective application rate of 11.7 g/m^2 of MITC (235 lb/ac of Basamid, 26.1 g/m^2 of dazomet). The highest emission ratio (9.93%) occurred in the first 6 hours during and after Basamid application although the duration time (6 hours) for this period was only half of those (12 hours) for other periods. The emission ratio for the first 18, 30, and 42 hours was 18.7%, 26.0%, and 30.5%, respectively (Table 11). The cumulative emission for 5 days of the study period was 43.1% of the applied MITC equivalent Basamid (Table 11 and Figure 10).

*18 hours for the first day

Figure 10. Cumulative MITC emission

Methyl Bromide

The model represented the four plots treated with methyl bromide and chloropicrin as four separate sources. Weather data for modeling started from 9:00 am, May 6 and ran to 7:00 am, May 11, 2005.

The modeling fluxes are listed in Table 12. The regressions of the measured and modeled concentrations were significant at P=0.05 for four of the ten sampling periods (Periods 1, 2, 4, and 7), but not significant for periods 3, 5, 8, 9, and 10. The data for these periods were sorted and regressed. Period 10 still could not achieve a significant regression, so the flux was estimated by dividing the sum of the measured concentrations by the sum of the modeled concentrations. During sampling Period 6, no measurable concentrations were detected and the flux was estimated to be 0. Flux was the highest (87.9 µg/m²-s) during the first period (application) and decreased over time except for periods 5 and 7. The 22-hour maximum TWA flux for sampling periods 1 and 2 was 84.6 µg/m²-s (Table 12).

The emission ratio for each sampling period, 24-hour, and cumulative period (Table 13 and Figure 11) was calculated based on the estimated flux and the effective application rate of 27.8 g/m² of methyl bromide (370 lb/ac of 67-33 Preplant Soil Fumigant with 67.0% methyl bromide). The highest emission ratio was 12.7% in the second sampling period. Although the highest flux was estimated during the first period, its duration time (10 hours) was 2 hours shorter than the second and other periods (12 hours). The emission ratio for the first 22, 34, and 46 hours was 24.1%, 31.3%, and 35.7%, respectively. The cumulative emission for 5 days of the study period was 53.4% of the applied methyl bromide equivalent 67-33 Preplant Soil Fumigant (Table 13 and Figure 11). No flux estimates or emission ratios were adjusted for trapping efficiency which was 50% for the charcoal tube method based on Biermann and Barry (1999).

Table 12. Modeling estimates of methyl bromide flux for air monitoring in Manteca

| Sampling Period | Duration (hours) | Time of day | Flux (µg/m²-s) | 24-hour TWA flux (µg/m²-s) |

Discussion of Measured and Modeled Results

MITC

The DPR's 8-hour exposure target level is $660 \mu\text{g}/\text{m}^3$ for MITC. In this study at a Basamid application rate of 235 lbs/ac, the highest individual air concentration was $129 \mu\text{g}/\text{m}^3$ during a 6-hour sampling period (Table 5). This result showed MITC air concentrations were lower than the DPR's 8-hour exposure target level. In another Basamid surface application study (Certis, 2003) with application rate of 307 lbs/ac ($14.8 \text{ g}/\text{m}^2$ of equivalent MITC), the highest individual air concentration was $348 \mu\text{g}/\text{m}^3$ during a 4-hour sampling period (Table 14). In another DPR study (Gurusinghe et al. 2008) the highest 4-hour concentration was $560 \mu\text{g}/\text{m}^3$.

The highest 24-hour TWA of measured MITC concentration (Table 8) and estimated flux (Table 10) occurred during the first sampling day. This pattern was similar to results from metam sodium studies (Wofford et al., 1994; ARB 1997; Saeed et al., 2000; Barry et al., 2004; Li 2004; and Levine et al., 2005). Another pattern similar to other MITC studies was that the measured air concentration (Figure 8) and the estimated flux (Figure 12) decreased dramatically after the first 24 hours, which indicates that dazomet conversion to MITC occurred rapidly although its molecular structure is more complicated than metam. This result was consistent with the reported dazomet hydrolysis half-life of 0.146 day at pH 7, 25 °C and aerobic soil half-life of 0.75 day in a pH 5.8, loamy sand soil (Table 1).

The maximum MITC air concentration (Figure 8) was mainly driven by the emission flux (Figure 12). The maximum MITC air concentration decreased over time regardless of day or night except following the lowest concentrations during period 6 (Figure 8). This contrasts with most metam sodium studies where MITC followed a diurnal pattern with air concentration increasing slightly during night sampling periods. The pattern of increased nighttime concentration in part may be due to nighttime stable atmospheric conditions accompanied by a surface based inversion (Barry, 2004; Levine et al. 2005). The lack of day/night diurnal pattern in this study is probably due to slightly higher average wind speed at nighttime than daytime in the first three days after application (Table 9) and due to generally decreasing fluxes (Table 10 and Figure 12). At the fourth night (period 8), maximum air concentration was higher than the preceding daytime maximum concentration (period 7) as shown in Figure 8. The average wind speed dropped by 2.79 meters/second correspondingly (Table 9). In another MITC study (Levine et al, 2005), no diurnal pattern occurred during the second treatment of metam sodium application to an untarped bedded field. The lowest concentration in period 6 (Figure 8) of this study was probably due to significant rain during sampling periods 5 and 6.

In comparing this study with other dazomet applications, the 6-hour maximum flux of this study was higher than 4-hour maximum fluxes of the two studies conducted by Certis (Table 14). The flux estimates for all three studies were confirmed through independent calculations (Wofford and Johnson, 2006). It appears that the differences of the two surface application studies conducted independently by Certis and DPR was larger than the two studies with different application methods and both conducted by Certis (Table 14). However, these comparisons could not be conclusive. During the two studies conducted by Certis, the calm winds may have added uncertainty to the ISCST3 modeling and made it difficult to produce strong regressions

between the measured concentrations and the modeled concentrations (Curtis, 2003). The maximum flux in this study was comparable to the maximum flux in Gurusinghe et al. (2008).

Several factors may contribute to high flux estimates in this monitoring study. The soil with low organic matter content and coarse texture of loamy sand promoted diffusion of MITC from soil to air due to larger pore space, lower moisture-holding capacity and number of adsorption binding sites. In addition, this study was conducted on 4 small, narrowed rectangular plots with dimensions of 100' x 22' and area of 0.05 acre each. The narrowed rectangular plots coupled with fairly consistent wind direction during application period (Figure 4), resulted in localized high concentrations downwind with a steep concentration gradient along the direction of longer sides of the plots. However, varying the wind direction to test the sensitivity of regressions indicated the fluxes were evidently not sensitive to these localized air concentrations. Detailed modeling for this pilot dazomet study was thoroughly discussed by Wofford and Johnson (2006). The higher edge to area ratio of the small plots compared to large fields may have some effects. For example, the application of dazomet through a spreader can lead to spills outside the intended area (Gurusinghe et al. 2008). In Gurusinghe et al. (2008) it was thought that an inadvertent spill near one of the monitors led to exaggerated concentrations. The high concentrations occurred when the monitor was upwind from the application area. If dazomet applications result in deposition of material outside of the measured boundaries of the plots, then this would more greatly impact the results in smaller plots compared to larger plots because the edge to area ratio is higher. For this reason, it would be preferable to conduct future studies on commercial scale fields (5-10 acres).

Table 14. Comparison of estimated flux and emission from four dazomet applications

| Application type | Effective application rate of MITC (g/m ²) | Maximum 4-hour TWA concentration (µg/m ³) | Maximum 4-hour Emission (µg/m ² -s) | % |
|-----------------------------|--|---|--|-------------------|
| Incorporated (Certis, 2003) | 29.1 | 1107 | 24.1-36.1 ^a | 1.19-1.79 |

^bmaximum 6-hour flux or concentration

^ccalculated 4-hour emission using the maximum 6-hour flux

Methyl Bromide

The DPR 24-hour exposure target level was 815 µg/m³ for methyl bromide. In this study at methyl bromide application rate of 248 lbs/ac, the highest individual air concentration was 133 µg/m³ during a 10-hour sampling period (Table 6) and a maximum 24-hour TWA air concentration of 103 µg/m³ (Table 8). These results showed methyl bromide air concentrations were lower than the DPR's 24-hour exposure target level.

Based on modeled flux, the estimated 24-hour maximum TWA emission of 26.3% was the highest among 14 methyl bromide studies with the same application method (Table 15). The estimated 24-hour maximum TWA emission for other 13 studies ranged from 4.9% to 24% and averaged 13%. Possible reasons for the high emission estimates relating to the soil properties in this monitoring study were discussed previously in the MITC section. Not surprisingly, the maximum 24-hour TWA concentration of this study was the lowest even though the application rate was the second highest among all studies listed in Table 15. This was due to the small field size (0.2 acre) of the application area. The higher flux for methyl bromide suggests the possibility that there are difficulties inherent to the small plot size, which could lead to higher measured flux values. However, unlike dazomet, methyl bromide was not applied via a spreader and therefore, it is more difficult to find mechanisms relating to plot size which may have induced higher flux estimates. It is possible that the higher flux estimates were an artifact of the many non-detects, which were at least partially due to the small plot size generating correspondingly small air concentrations. As with MITC, it would seem prudent to conduct future studies on larger plots.

^bEstimated as percentage of applied methyl bromide, and unadjusted for 50% of trapping efficiency (Biermann and Barry, 1999).

^cCalculated 24-hour emission using the maximum TWA 22-hour flux.

One objective for monitoring methyl bromide in this study was as a reference to dazomet regarding their emission patterns. Sampling for these two chemicals was collocated throughout the entire monitoring period. Statistical analysis showed that the measured MITC and methyl bromide air concentrations were significantly correlated ($p < 0.001$, $r = 0.63$, $n = 122$). Their maximum concentrations during each sampling period were also significantly correlated ($p < 0.001$, $r = 0.935$, $n = 10$). Similar to dazomet, the highest 24-hour TWA of measured methyl bromide concentration (Table 8) and modeled flux (Table 12) occurred during the first sampling day. The concentrations (Figure 8) and estimated flux (Figure 12) decreased dramatically after the first 24 hours although the decline rates were slightly different from dazomet.

Figure 12. Model estimated flux for MITC and methyl bromide

CONCLUSION

For MITC, the highest individual sample concentration, $129 \mu\text{g}/\text{m}^3$, in the first 6-hour during and after Basamid application were lower than the DPR's 8-hour MITC exposure target level, $660 \mu\text{g}/\text{m}^3$. Based on the modeling flux estimates, the highest emission ratio, 9.89%, occurred in the first 6 hours during and after Basamid application. The cumulative emission for 5 days of the study period was 43.1% of the applied MITC equivalent Basamid.

Similar to other MITC studies including metam sodium studies, the highest 24-hour TWA of measured MITC concentration and estimated flux occurred during the first sampling day, and decreased dramatically after the first 24 hours. This indicates that dazomet conversion to MITC occurred rapidly. Unlike most of other MITC studies which followed an apparent diurnal pattern with air concentration increasing slightly during night sampling periods due to wind speed decrease at nighttime, the dominant pattern of maximum MITC air concentration in this study was declining over time because of declining of the estimated fluxes and slightly higher average wind speed at nighttime than daytime in the first three days after application.

For methyl bromide, the highest maximum 24-hour of TWA concentration, $103 \mu\text{g}/\text{m}^3$, during the first sampling day (22 hours), was lower than the DPR's 24-hour exposure target level, $815 \mu\text{g}/\text{m}^3$. Based on modeled flux, the estimated 24-hour maximum TWA emission of 26.3% was twice as high as the average of the other 13 methyl bromide studies. The cumulative emission for 5 days of the study period was 53.4% of the applied methyl bromide.

For both MITC and methyl bromide, the patterns of measured concentrations and modeled emission fluxes over time were parallel and significantly correlated. Their maximum concentrations during each sampling period were also significantly correlated. In addition, the modeled flux and emission ratio of both chemicals were higher than other MITC and methyl bromide studies, respectively.

The small size and configuration of the application area may have impacted study results. The large fraction of methyl bromide samples below the detection limit was probably due to the small size of the application areas and the consequent small mass of methyl bromide that was applied. The non-detect samples made it difficult to produce significant regressions for the purposes of flux analysis. For MITC, the small plots may have led to higher flux estimates because the method of dazomet application may lead to inadvertent spillage at the plot edges. This could have a relatively larger effect on small plots, where the perimeter-to-area ratio is relatively higher than in larger fields. Future studies should probably utilize larger plots, more consistent with commercial applications.

SUBJECT: MODELING RESULTS FOR THE 2005 DAZOMET AND METHYL
BROMIDE MONITORING STUDY IN MANTECA.

General

The U.S. EPA ISCST3 dispersion model was used, as described by Johnson (1999), to estimate metam sodium and methyl bromide flux associated with a dazomet and methyl bromide application in Manteca, CA in 2005. The model requires data input for the treatment areas (source), sampling locations (receptors) and meteorological data (Met1® data). The treatment areas and receptors were mapped out with an x and y coordinate system. The Met1® meteorological weather data collected was averaged over 1 hour intervals. The model results and measured results were compared through regression analysis to determine the multiplying factor (the slope of the regression line) used to calculate the flux factor. There was significant rain during intervals 5 and 6.

MITC modeling results

The treatment areas were represented as four separate sources, with an initial emission rate of 100 ug/m²s at ground level. Meteorological data was measured near the field with a Met1® weather station. Application to the four treatment areas commenced at approximately 12:45 pm, therefore, the met file data for period 1 started at 1:00 pm. The results of the regression analysis of the measured concentrations and the modeled concentrations are listed in Table 1. The regressions were significant for most of the sampling intervals. Sampling interval 8 did not result in a regression with a significant relationship so the concentrations were sorted from lowest to highest and reanalyzed. The 18-hour time weighted average (TWA) for sampling intervals 1 and 2 was 33.8 µg/m²-s (Table 2). The flux rate was highest during the application interval and decreased over time (Figure 2).

Table 1. Regression results for 2005 MITC monitoring in Manteca

| Sampling Interval | Duration (hrs) | Flux ($\mu\text{g}/\text{m}^2\text{-s}$) | R^2 | F-test p-value | Time of Day |
|-------------------|----------------|--|-------|----------------|-------------|
| 1 | 6 | 53.79 | 0.93 | <0.001 | Day |
| 2 | 12 | 23.76 | 0.86 | <0.001 | Night |
| 3 | 12 | 19.65 | 0.76 | <0.001 | Day |
| 4 | 12 | 12.25 | 0.90 | <0.001 | Night |
| 5 | 12 | 11.82 | 0.89 | <0.001 | Day |
| 6 | 12 | 1.561 | 0.36 | 0.040 | Night |
| 7 | 12 | 9.369 | 0.73 | <0.001 | Day |
| 8 | 12 | 3.777 | 0.88* | ** | Night |
| 9 | 12 | 6.062 | 0.79 | <0.001 | Day |
| 10 | 12 | 1.556 | 0.81 | <0.001 | Night |

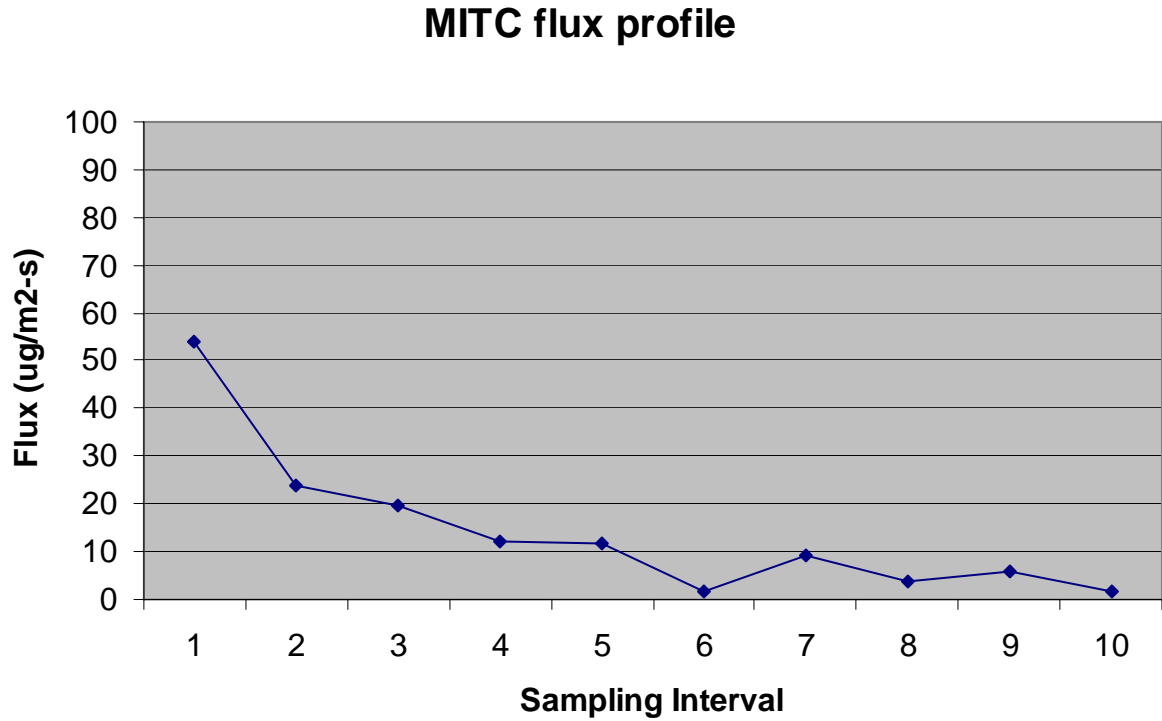

*Concentrations were sorted before regression analysis.

**p value cannot be calculated using conventional statistics.

Table 2. 18-hour Time Weighted Average of flux calculation for MITC monitoring.

| Sampling Interval | Duration (hrs) | 24-hr TWA flux ($\mu\text{g}/\text{m}^2\text{-s}$) |
|-------------------|----------------|--|
| 1 | 6 | |
| 2 | 12 | 33.8 |

Figure 1. Flux profile for MITC at each sampling interval.

Methyl bromide modeling results

The treatment areas were represented as four separate sources, with an initial emission rate of 100 $\mu\text{g}/\text{m}^2\text{-s}$ at ground level. Application to the four treatment areas commenced at approximately 9:00 am, therefore, the met file data for period 1 started at 9:00. The results of the regression analysis of the measured concentrations and the modeled concentrations are listed in Table 3. The regressions were significant to the 5% level for four of the sampling intervals (Intervals 1, 2, 4, and 7). Sampling intervals 3, 5, 8, 9 and 10 did not result in a regression with a significant relationship so the concentrations were sorted from lowest to highest and reanalyzed. The regression of interval 10 did not result in a significant relationship. During interval 6 there were no measurable concentrations of methyl bromide detected, therefore, the flux was estimated to be 0. The 22-hour time TWA for sampling intervals 1 and 2 was 84.6 $\mu\text{g}/\text{m}^2\text{-s}$ (Table 2). The flux rate was highest during the first night following application and decreased over time (Figure 2).

Table 3. Regression results for 2005 methyl bromide monitoring in Manteca

| Sampling Interval | Duration (hrs) | Flux ($\mu\text{g}/\text{m}^2\text{-s}$) | R^2 | F-test p-value | Time of Day |
|-------------------|----------------|--|-------|----------------|-------------|
| 1 | 10 | 87.85 | 0.83 | <0.001 | Day |
| 2 | 12 | 81.83 | 0.90 | <0.001 | Night |
| 3 | 12 | 46.18* | 0.83 | ** | Day |
| 4 | 12 | 28.21 | 0.72 | <0.001 | Night |
| 5 | 12 | 37.14* | 0.78 | ** | Day |
| 6 | 12 | 0 | ** | ** | Night |
| 7 | 12 | 37.90 | 0.68 | <0.001 | Day |
| 8 | 12 | 23.68* | 0.86 | ** | Night |
| 9 | 12 | 10.45 | 0.42 | 0.02 | Day |
| 10 | 12 | 5.00*** | | | Night |

¹ No measurable amounts were detected during interval. Unable to calculate regression.

*Concentrations were sorted before regression analysis.

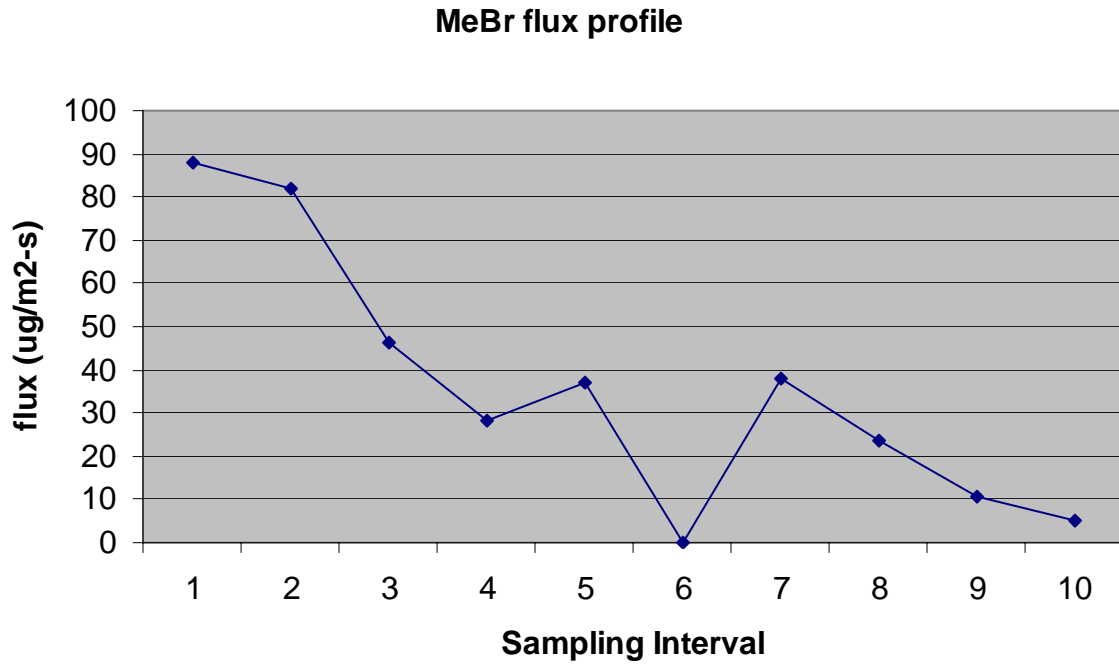

**p value cannot be calculated using conventional statistics.

***flux estimated by dividing sum of the measured concentrations by the sum of the modeled concentrations.

Table 4. 24-hour Time Weighted Average of flux calculation for methyl bromide.

| Sampling Interval | Duration (hrs) | 22-hr TWA flux ($\mu\text{g}/\text{m}^2\text{-s}$) |
|-------------------|----------------|--|
| 1 | 10 | |
| 2 | 12 | 84.6 |

Figure 2. Flux profile for methyl bromide at each sampling interval.
